PURPOSE. To investigate longitudinal changes of subbasal nerve plexus (SNP) morphology and its relationship with conventional measures of neuropathy in individuals with diabetes.

METHODS. A cohort of 147 individuals with type 1 diabetes and 60 age-balanced controls underwent detailed assessment of clinical and metabolic factors, neurologic deficits, quantitative sensory testing, nerve conduction studies, and corneal confocal microscopy at baseline and four subsequent annual visits. The SNP parameters included corneal nerve fiber density (CNFD), branch density (CNBD), and fiber length (CNFL), and were quantified using a fully automated algorithm. Linear mixed models were fitted to examine the changes in corneal nerve parameters over time.

RESULTS. At baseline, 27% of the participants had mild diabetic neuropathy. All SNP parameters were significantly lower in the neuropathy group compared with controls (P < 0.05). Overall, 89% of participants examined at baseline also completed the final visit. There was no clinically significant change to health and metabolic parameters and neuropathy measures from baseline to the final visit. Linear mixed model revealed a significant linear decline of CNFD (annual change rate, −0.9 nerve/mm2, P = 0.01) in the neuropathy group compared with controls, which was associated with age (β = −0.06, P = 0.04) and duration of diabetes (β = −0.08, P = 0.03). In the neuropathy group, absolute changes of CNBD and CNFL showed moderate correlations with peroneal conduction velocity and cold sensation threshold, respectively (r = 0.38 and 0.40, P < 0.05).

CONCLUSIONS. This study demonstrates dynamic small fiber damage at the SNP, thus providing justification for our ongoing efforts to establish corneal nerve morphology as an appropriate adjunct to conventional measures of diabetic peripheral neuropathy.

Keywords: corneal confocal microscopy, diabetes, natural history

Diabetic neuropathy is a substantial and burdensome complication of diabetes, affecting up to 50% of these individuals.1 Diabetic peripheral neuropathy (DPN), which is the most common form of neuropathy, manifests as a distal, symmetric polyneuropathy that begins in the lower extremities and may progress proximally.2 Diabetic peripheral neuropathy leads to morbidity in diabetic patients in the form of painful neuropathy and foot ulceration with consequent lower limb amputation.3 It accounts for reduced quality of life and imposes a significant economic burden that affects both individuals and society.3,5

Several established tests are commonly used for screening, detection, and assessment of DPN and to monitor its progression. Most of these tests examine neuronal function; however, direct observation of nerve structure also is possible. Neurologic symptoms and signs, quantitative sensory tests (QST), and nerve conduction studies (NCS) are the most commonly used tests for DPN.6 Indeed, symptoms, neurologic deficits, and NCS constitute the basis on which diabetic neuropathy is diagnosed. Quantitative sensory tests provide quantitative measures of sensation; however, these tests require cooperation and concentration of the examinee and they also may be affected by anthropometric variables.7 Although recent studies have shown that the proficiency of QST assessment is adequate,8 the reproducibility of symptoms and signs9 and NCS10 has been shown to be limited. Furthermore, studies in patients with impaired glucose tolerance (IGT)11 and recently diagnosed type 2 diabetes12 show a marked small fiber neuropathy accompanying large fiber dysfunction.

Quantification of nerve pathology is possible through direct morphometric examination of nerves, including sural nerve biopsy13 and skin biopsy,14 However, these techniques are
invasive, require expertise for quantification, and cannot be repeated from the same site for longitudinal studies. Accurate detection and estimation of progression are needed, especially to test putative treatments, which may alleviate the condition, and/or prevent or delay the development of sequelae. As reviewed in more detail elsewhere,15,16 based on the pathogenesis of DPN, several potential therapeutic approaches have been developed targeting these mechanisms; however, apart from glucose control and pain management, currently there is no approved treatment for DPN.15,17

Lack of a sensitive, accurate, and reliable clinical end point has been one of the obstacles in mounting treatment trials for DPN.18 Growing evidence supports a prominent association between corneal subbasal nerve plexus (SNP) morphology measured with corneal confocal microscopy (CCM) and DPN. Corneal confocal microscopy as a quick, noninvasive, and reiterative technique has a demonstrated capacity to detect early small nerve fiber damage in diabetic patients,19 and diagnose20–22 and classify severity of DPN.23,24 Conventional measures of neuropathy and corneal nerve parameters also are related.21,23,25 Furthermore, the demonstration of early corneal nerve regeneration following simultaneous pancreas and kidney transplantation26 and optimized glycemic and lipid control in an observational study27 suggest that CCM may well fulfill some of the criteria for a surrogate end point for diabetic neuropathy.

To our knowledge, no study has been conducted to date concerning the natural course of the SNP structure over time in diabetic patients. Therefore, in this study, we sought to investigate the natural history of the SNP morphology in type 1 diabetic individuals without and with mild neuropathy. Furthermore, the longitudinal relationship between changes in corneal nerve structure and established measures of neuropathy in individuals with diabetes also was addressed.

METHODS

Study Design and Participants

This prospective, observational, longitudinal study was conducted following approval from Queensland University of Technology, Princess Alexandra Hospital, and Mater Hospital research ethics committees as a part of the LANDMark study28 in Brisbane, Australia. Before their enrollment, written informed consent was obtained from all participants and the research adhered to the tenets of the Declaration of Helsinki. Based on the inclusion/exclusion criteria, 147 type 1 diabetic participants were recruited from the Diabetes and Endocrinology Research Centre at Princess Alexandra and Mater hospitals and the general population in Brisbane. Sixty healthy participants, without peripheral neuropathy and/or diabetes also were recruited as controls. All participants were assessed at baseline and assessments continued for four annual subsequent visits (five time points in total and approximately 960 case visits). Participants were excluded in this study for any of the following: history of ocular trauma or surgery, ocular disease or systemic disease with potential corneal effect, and systemic disease (other than diabetes). Other causes of neuropathy were excluded. Diabetic participants with moderate and severe neuropathy also were excluded. All participants underwent neurologic and medical evaluation as well as ocular screening (visual acuity, slit lamp examination, and IOP) and CCM, which were repeated annually.

For the definition of DPN, we followed accepted criteria29 that rely on the presence of abnormal electrophysiological finding, based on age-matched controls at the site, in addition to clinical signs and/or symptoms, which were defined as one or more of the following: neuropathy disability score (NDS) of 5 or more of 10,30 or diabetic neuropathy symptom score (DNSS) of 1 or more of 4.31 The methods used during this study to assess neuropathy and clinical and metabolic factors have been reported in detail elsewhere28 and will be described only briefly here.

Assessment of Neuropathy

Neuropathy Signs and Symptoms. The NDS, which is a scale of 0 to 10, was used to assess neurological deficits. This measure included assessment of vibration, pin-prick, and temperature perception as well as presence or absence of ankle reflexes in both lower limbs. Diabetic neuropathy symptom score, a scale of 0 to 4, was used to assess symptoms of neuropathy.

Quantitative Sensory Tests. Quantitative sensory tests comprised of vibration perception, measured on the plantar surface of the big toe, and thermal (warm and cold) sensation which was assessed on the dorsal surface of the foot on the hand-dominant side.

Nerve Conduction Studies. Peroneal motor nerve conduction velocity (ankle to fibula head), amplitude (ankle to extensor digitum brevis), and F-wave latency were determined on the hand-dominant side of the participants.

General Health and Metabolic Assessment

At each visit, all participants underwent assessment of height, weight, body mass index (BMI), blood pressure, HbA1c, and lipid profile.

Corneal Confocal Microscopy and Image Analysis

Corneal confocal microscopy was carried out using the Rostock Cornea Module in combination with an HRT 3 confocal microscope (Heidelberg Engineering, Heidelberg, Germany). Eight images of the SNP, showing in focus nerves and not overlapping more than 20%,32 were acquired from the center of cornea on the hand-dominant side using manual focusing and section mode. Automatic segmentation and quantification of the SNP parameters, including corneal nerve fiber density (CNFD), branch density (CNBD), and fiber length (CNFL), were performed using ACCMetrics (University of Manchester, Manchester, UK),33 which is a fully automated analytical system. The SNP parameters for each participant were the average value obtained from the eight captured images and expressed in the unit of number per millimeter squared for CNFD and CNBD, and millimeter per millimeter squared for CNFL.

Intra- and Interobserver Repeatability of the SNP Parameters

To ascertain the repeatability of the SNP parameters from one time to another, test-retest was carried out by performing CCM examination and automated image analysis for 16 participants, including 10 with diabetes and 6 healthy controls by a single operator as described above. Each participant was examined twice, on the same day of examination, at least 30 minutes apart. No significant differences were found between test and retest measurements for CNFD, CNBD, and CNFL (P = 0.59, P = 0.88, and P = 0.94, respectively). The intraclass correlation coefficients (ICC) and coefficient of repeatability (CoR) were 0.81 and 0.08 for CNFD, 0.84 and 0.20 for CNBD, and 0.90 and 0.03 for CNFL, respectively.

To assess the interobserver reproducibility of the SNP parameters, 11 participants (6 with diabetes and 5 healthy
controls) underwent CCM examinations twice by two experienced operators on the same day of examination. The differences of the SNP parameters were not statistically significant for two observers (CNFD, \( P = 0.29 \); CNBD, \( P = 0.22 \) and CNFL, \( P = 0.21 \)). The estimated ICC and CoR were 0.87 and 0.10 for CNFD, 0.93 and 0.23 for CNBD, and 0.94 and 0.04 for CNFL, respectively. Overall, CNFL and CNFD achieved the highest values for repeatability and reproducibility, whereas CNBD showed an acceptable consistency within and between observers.

### Statistical Analysis

Normality of the data was examined using the Kolmogorov-Smirnov test and the appropriate test was applied for analysis. Data are presented as mean \( \pm SD \) or median and interquartile range. Four sets of analyses were conducted. First, the demographic and clinical characteristic variables were compared between control and diabetic groups as well as between baseline and final visit. Second, using Toronto criteria, participants with diabetes were stratified into those without DPN (DPN–ve) and with DPN (DPN+ve). Corneal nerve parameters and established neuropathy measures were compared among control, DPN–ve, and DPN+ve. For the purpose of the aforementioned analyses, parametric data were included as a time-invariant predictor variable to explore any group differences over time.

The association between the initial CNFD parameter and the change in this parameter was estimated by calculating the covariance matrix. Here, the “variance components” option was chosen and also the restricted maximum likelihood estimates for parameters was used. The process of the aforementioned model was repeated for CNBD and CNFL. Depending on whether the time*group interaction was statistically significant or not, a second set of fixed effects, namely, sex, age at enrollment, duration of diabetes, HbA1c, lipid profile, blood pressure, BMI, alcohol and tobacco consumption, were included and their effects were examined. A stepwise elimination of the variables with nonstatistically significant \( P \) values also was applied.

The relation between risk factors and the changes of SNP parameters in diabetic individuals, regardless of their neuropathy status, was analyzed with the latter model where all relevant risk factors were included. Control participants were excluded and group, as factor, was also removed from the model.

Finally, to explore the relationship between changes in corneal nerve parameters and functional measures of neuropathy, absolute change in all parameters was calculated \( (\Delta \text{parameter} = \text{parameter value at final visit} - \text{parameter value at baseline}) \). Bivariate correlations between absolute change of corneal nerve parameters and neuropathy measures were estimated using Pearson \( r \) and Spearman’s rho correlation coefficients, where appropriate.

The IBM SPSS 21 (IBM SPSS Statistics, IBM Corporation, Chicago, IL, USA) was used for all statistical tests and a two-tailed \( \alpha = 0.05 \) level of significance was considered for all analyses.

### Results

Table 1 shows the clinical characteristics and demographic data of participants with diabetes and controls at baseline and final visit. Approximately 95% of the entering participants were Caucasians of European descent. There was no significant difference between the mean age of participants with diabetes and controls \( (P = 0.11) \). There were no statistically significant

differences between diabetes and control groups with respect to high-density lipoprotein (HDL), triglycerides, diastolic blood pressure (BP), BMI, and number of cigarettes smoked per day (P > 0.25). Compared with controls, individuals with diabetes had a higher HbA1c (% NGSP) (P < 0.001) and systolic BP (P = 0.03) and lower total cholesterol (P < 0.001), low-density lipoprotein (LDL) (P < 0.001), and alcohol consumption (P = 0.001).

The number of participants attending annual visits is depicted graphically in Figure 1. Altogether, 184 participants (89% of the baseline participants) completed the final visit. Personal decision was the main reason for withdrawal (13% of the baseline participants) completed the final visit.

As can be seen from Table 1, at final visit HbA1c showed a clinically insignificant decrease in controls (mean difference 0.2%, P < 0.001), whereas it remained the same in participants with diabetes (P = 0.65). Lipid profile, BP, height, and alcohol consumption did not differ at final visit compared with baseline visit for both diabetes and control groups (P > 0.05). Although BMI showed a statistically significant increase at the final visit in participants with diabetes (P = 0.02), there was no change in controls (P = 0.42). Both control and diabetic participants reported less smoking (number of cigarettes per day) at the final visit compared with baseline (P = 0.001).

Comparison of the mean or median change from baseline to final visit in neuropathy measures of individuals with diabetes showed that there were no significant changes in DNSS (median 0 [0.0–0] vs. 0 [0–0], P = 0.56), cold sensation threshold (median 28.5 [24.8–28.5] vs. 28.5 [26.0 vs. 28.5] °C, P = 0.85), vibration threshold (median 6.8 [2.5–6.8] vs. 6.6 [2.9–6.6] Hz, P = 0.42) and peroneal F-wave latency (mean 52.0 ± 5.1 ms vs. 52.2 ± 7.7 ms, P = 0.85). Neuropathy disability score (median 1.0 [0.0–1.0] vs. 0.0 [0.0–0.0], P < 0.01), warm sensation threshold (median 37.6 [34.9–37.6] vs. 36.2 [34.8–36.6] °C, P < 0.01) and peroneal amplitude (mean 4.6 ± 2.6 vs. 5.0 ± 2.5 mV, P = 0.03) showed slight but significant improvements, whereas peroneal nerve conduction velocity (mean 45.3 ± 6.0 vs. 44.4 ± 5.8 m/s, P = 0.03) was the only measure that declined significantly from baseline to final visit.

Using Toronto criteria, in 147 individuals with type 1 diabetes, 39 (27%) were diagnosed with DPN at baseline. Table 2 delineates the outcomes of the SNP parameters and neuropathy assessment by DPN status. Subbasal nerve plexus parameters were significantly reduced in DPN–ve and DPN+ve groups compared with controls (P < 0.01). All established neuropathy measures were significantly different between groups. Quantitative sensory tests, peroneal F-wave latency, and peroneal amplitude displayed greater deficits in the DPN+ve group compared with DPN–ve and control groups (P < 0.05). Peroneal nerve conduction velocity was significantly lower in both DPN–ve and DPN+ve groups compared with controls and there was also a significant difference between DPN–ve and DPN+ve groups (P < 0.05). Neuropathy disability score and DNSS were significantly higher in DPN+ve group compared with control and DPN–ve groups (P < 0.001).

Figure 2 illustrates the 4-year time course for the SNP parameters in the cohort by neuropathy status. The results of the three created basic linear mixed model (LMM) analyses for CNFD, CNBD, and CNFL can be found in Table 3. The Type III tests of fixed effects shows overall test of significance for the predictors included in the three basic models (LMM 1–3). There was a significant effect of group for all three models; however, the effect of time was not significant for any of them. The Type III F-test for the interaction between group and time was significant only in LMM1; therefore, no more models were fitted for CNBD and CNFL as response variables.

A second subset of fixed effects was included in LMM1. On sequential removal of nonstatistically significant fixed effects and considering the lower resultant Akaike’s information criteria for comparing alternative models, a final model (LMM4) contained the fixed effects of group, time, age, duration of diabetes, HbA1c, and the group*time interaction was fitted. Parameter estimates and corresponding SEs, P values and 95% confidence intervals are given in Table 4. Group and time did not show a significant effect, whereas the effects of age at enrollment (β = −0.06, P = 0.04) and duration of diabetes (β = −0.08, P = 0.03) were significant. The LMM4 also showed a differential effect of time on the trajectory of CNFD with the slope decreasing by 0.91 nerve/mm² for DPN+ve individuals compared with controls (the reference level of the group).

The examination of significant risk factors for corneal neuropathy in diabetic individuals, irrespective of the baseline neuropathy status, showed that CNFD was associated with HbA1c (β = −0.58, P = 0.03) and duration of diabetes (β = −0.08, P = 0.03). Corneal nerve branch density was found to be affected by the duration of diabetes (β = −0.21, P = 0.01) and smoking (β = −0.25, P = 0.04). No statistically significant

Because peroneal nerve conduction velocity was the only measure that showed a significant worsening in the diabetes group, we sought to compare the trajectories of this parameter between groups using an additional mixed model (LMM5). The above-mentioned basic model was repeated with peroneal nerve conduction velocity as the response variable. There was a significant effect of time ($P < 0.01$) and group ($P < 0.01$), but the group*time interaction was not significant ($P = 0.92$), indicating that the observed time effect is not different between groups.

In the diabetic group, bivariate correlation revealed a modest association between absolute changes of CNBD and peroneal nerve conduction velocity (Pearson $r = 0.25$, $P = 0.02$). In the DPN+ve group, there was a significant correlation between CNBD and peroneal nerve conduction velocity (Pearson $r = 0.38$, $P = 0.05$). The absolute change in CNFL was also positively correlated with the cold sensation threshold (Pearson $r = 0.40$, $P = 0.03$).

**DISCUSSION**

In vivo assessment of the SNP morphology using CCM has emerged as a valuable clinical modality to improve our understanding of the relationship between this rich nerve plexus and various ocular and systemic conditions and diseases. As reviewed in more detail elsewhere,35,36 morphometric evaluation of the SNP has been used to diagnose, assess, and follow-up ocular surface conditions, including ocular allergy, dry eye, infectious keratitis, and glaucoma and after keratorefractive surgery and contact lens wear. Currently, considerable evidence exists that advocates the utility of CCM for assessment of small nerve fiber pathology induced by systemic and neurological conditions, in particular DPN. This study examined the longitudinal aspect of the utility of CCM to serve as an acceptable measure of DPN in clinical research and practice.

We report data from a cohort of individuals with type 1 diabetes ($n = 147$) and healthy controls ($n = 60$) collected from baseline to a median duration of 3.7 years. Although the
Corneal Nerve Changes in Diabetic Neuropathy

patients as compared with controls is attributed to the fact that 35% were receiving lipid-lowering medications.

Comparison of the clinical parameters at baseline and final visit showed that there were no clinically significant changes to health or metabolic and anthropometric measurements, indicating stable glucose control and desirable maintenance of cardiovascular risk factors. Although the Hawthorne effect may have been involved, the finding of lower alcohol consumption in the diabetic patients at baseline, which is maintained at follow-up, reflects good diabetes education. And the significant reduction in tobacco consumption over time in both diabetic patients and control subjects presumably reflects overall population level of education to stop smoking.

Except for peroneal nerve conduction velocity, with a statistically significant but clinically trivial decline (−0.9 m/s), the remaining established measures of neuropathy remained unchanged or improved slightly from baseline to the final visit. However, LMM5 showed that changes in peroneal nerve conduction velocity in DPN+ve and DPN−ve patients did not differ significantly from controls, indicating a similar effect of time for groups. The low rate of change over time in these measures may be attributed to the following: the maintenance of a healthy lifestyle and compliance with medical advice among our diabetic cohort, the inclusion of participants with only mild neuropathy, and the relatively short duration of study. Negligible worsening or no progression of the traditional measures of DPN also has been observed in the placebo arm of a recent interventional study of 227 patients with predominantly type 2 diabetes, but with substantially worse glycemic control at baseline (8.8% ± 1.9%) and a reduction of 0.67% ± 1.41% over 4 years. Our findings are further supported by a 3-

Corneal Nerve Changes in Diabetic Neuropathy

The baseline cross-sectional findings in the present study confirmed that all three SNP parameters were reduced in the neuropathy group compared with controls. The parameter that underwent the most marked reduction over time was CNFD. This suggests that branch damage (thinner branches emanating from major nerves) might represent the primary pathological change in DPN, whereas CNFD (a parameter related to the major nerve trunks) deterioration occurs later. The reduction in CNFD along with a nonsignificant decline of the other two parameters also may suggest degeneration of major nerve trunks with concomitant regeneration reflected by an increase in the CNBD and CNFL. Therefore, it is conceivable that loss and indeed repair of different SNP parameters may occur at different stages of the disease.

Limited studies are available documenting the link between corneal small nerve fiber change and risk factors of DPN. In the present study, when the data were restricted to include only diabetic individuals and on removal of the effect of group in the LMMs, we found that every 1-unit increase of HbA1c was associated with a decrease of approximately 0.6 nerve/mm² in CNFD. There also was a negative effect of diabetes duration on CNFD and CNBD. Each 10-year increase of diabetes duration at baseline resulted in 0.8 and 2.0 nerve/mm² decline of central corneal CNFD and CNBD, respectively. Corneal nerve branch density was also significantly affected by smoking. Increasing one cigarette per day had a negative effect of 0.25 nerve/mm².

These results demonstrate the link between risk factors of DPN and morphologic parameters of corneal nerves. We have no clear explanation why HbA1c has an effect on CNFD, but not CNBD and CNFL. Nevertheless, this finding is consistent with the study of Tavakoli et al. who reported a significant correlation between changes in HbA1c and CNFD (r = -0.52, P < 0.01) but not for CNBD and CNFL. In a study of 38 type 1 diabetic patients with and without neuropathy, Ishihashi et al. reported time-dependent effects of HbA1c on SNP parameters. Although nerve conduction latency was positively correlated with the mean HbA1c levels at time of, or up to 3 months before CCM examination, no significant association was found between CNFD and CNFL with HbA1c up to 6 years before CCM examination.

These findings emphasize the importance of including different SNP parameters in future studies, where these parameters are to be used as measures of small nerve fiber damage and in particular repair. Additionally, in this study, only the central cornea has been investigated. Recent studies have revealed that loss of corneal nerve structure in the SNP mainly occurred at the inferior whorl, which is slightly more distal than the central cornea and may therefore be expected to show more marked pathology. Further longitudinal work assessing the inferior whorl as opposed to the central cornea may provide additional insights and ability to discriminate change in relation to DPN.

In previous cross-sectional studies, SNP parameters have been shown to correlate with functional and structural measures of neuropathy. Quattrini et al. reported a significant correlation between CNFD versus NDS (r = -0.30, P = 0.05) and cold sensation threshold (r = -0.40, P < 0.01). In a subsequent study, moderate correlations were found between NDS and corneal nerve parameters (r = -0.48 to -0.58; P < 0.001). In a recent study by Sivakandarajah et al., CNFD, CNBD, and CNFL were related to cold sensation threshold (r = 0.32 to 0.37; P ≤ 0.01). In this longitudinal study, we examined the relationship of change in corneal nerve parameter with conventional measures of neuropathy by calculating the absolute change from baseline to final visit for participants with diabetes. We found a modest correlation between CNBD and peroneal conduction velocity (Pearson r = 0.23, P = 0.02). When the data were restricted to the DPN+ve group, this correlation increased to 0.38. Furthermore, CNFL also correlated with cold sensation threshold (r = 0.40, P = 0.03), which indicates that SNP parameters do change in a fashion comparable with some traditional measures of neuropathy.

The key strengths of this study are its longitudinal nature, inclusion of a range of traditional neuropathy measures (small and large nerve fiber dysfunction) in a relatively large number of type 1 diabetic participants, the consistency and strict adherence to technical and methodological procedures, such as capturing and selection criteria of the SNP images, and using a fully automated image analysis algorithm, which is essential to eliminate the variability associated with manual and semi-
Corneal Nerve Changes in Diabetic Neuropathy

automated analysis. Thus, we used a fully automated image analysis algorithm that has been validated and compared against the manual and semi-automated analysis in individuals with diabetes.

A limitation of this study is that most type 1 participants were enrolled from specialized clinics, where the glycemic and cardiovascular factors were optimally controlled, which may not represent the typical population with type 1 diabetes. Additionally, 4 years of study might be insufficient to discern changes over time, particularly in the case of patients with mild neuropathy or the limited number of apparently motivated participants with well-controlled diabetes available in the neuropathy group.

In conclusion, the findings presented herein provide evidence that CCM has the potential to track the structural alterations of the small nerve fibers in DPN. Furthermore, these findings support the notion that quantification of the SNP morphology has a substantial potential to be used as an appropriate adjunct measure to conventional measures of DPN.
