Abstract

The response of Awassi ewes to graded amounts of supplementary concentrate diet was examined for the first 12 weeks of lactation. The growth rate of lambs and their health status were also investigated. Seventy-five ewes were divided into three equal groups and given a basal roughage diet of shredded alfalfa straw at a rate of 750 g dry matter (DM) per ewe per day supplemented with a concentrate diet at three amounts, 900 g (low), 1350 g (medium) and 1800 g (high) of DM per ewe per day starting at the beginning of lactation. Ewes were adapted to the diet by feeding daily at a rate of 200 g per ewe during the last 6 weeks of pregnancy. The concentrate was estimated to contain 12.6 MJ of metabolizable energy and 382 g of crude protein per kg DM. Ewes and their offspring were housed in a partly enclosed yard. Lambs remained with their dams continuously except for the days of milk yield measurements, when they were separated from the dams for 11 or 12 h. The eyes were examined for subclinical mastitis and the incidence of scouring in lambs was recorded.

Ewes given the high level of concentrate produced more (P < 0.05) milk but differences between medium and low groups were significant only up to week 4 of lactation. Total milk yields during the 9 weeks test period were 583, 704 and 833 kg for the low, medium and high groups, respectively. Ewes suckling twins produced more (P < 0.05) milk than ewes suckling singlets. The rate of weight loss was lower (P < 0.05) for ewes given the high feeding regime; three equipped their immediate post-calving body weight by week 10. Sex of lambs and litter size had no effect on body weight loss but early nursing twins tended to lose more weight during the 12 weeks suckling period. Lamb growth rates were similar (P > 0.05) across treatments. The daily intake of concentrate by the ewes did not affect the incidence of scouring in lambs or mastitis in ewes.

On both economical and biological grounds it is recommended to offer concentrate during the first 9 weeks of lactation at levels >900 g per ewe per day in order to produce an appreciable yield of milk and restore a positive energy balance early in the true lactation period.

Keywords: Awassi, body weight, growth rate, mastitis, milk yield, sheep.

Introduction

The Awassi sheep is the most popular fat-tail dairy breed in Middle Eastern and Arab countries. The breed has been introduced recently into New Zealand and Australia because of an increasing demand for sheep milk, cheese, other dairy products and growing preference for Awassi meat. The Awassi sheep is well known for its adaptability to harsh, semi-arid and arid environments, resistance to diseases, flocking instincts and ability to travel long distances. The breed is kept traditionally for the production of milk, meat and wool, and plays a significant socio-economic role, which extends the importance of cattle and goats in Jordan and neighbouring countries.

Milk may come after meat in importance but its demand is growing. Milk goes either into home use or processing into cheese, dried yoghurt (laagrad) and cheese which is a traditional industry in the
Middle East. Prices of dairy products from sheep milk exceed those from cow milk. Limited information is available on the effect of nutrition on milk yield, body-weight change, health status of Awassi ewes and the growth of their lambs.

The experiment described here examined the effect of feeding Awassi ewes different amounts of concentrate for the first 9 weeks of lactation on milk yield and body-weight change in the ewes and growth rate of the lambs over 12 weeks of lactation. The health status of ewes and their lambs were examined also.

Material and methods

Animals

Seventy-five Awassi ewes, aged between 3 and 5 years with a mean post-lambing weight of 66±6 (s.d. 8/93) kg, were allocated to three equal groups according to age, weight and type of birth (single or twin). Milk yield measurements were made over a 24-h period and repeated weekly over the first 9 weeks of lactation. Ewes and their offspring were housed in a partially enclosed yard. Lambs remained with their dams continuously except for the days of milk measurements and had restricted access to a creep diet. All lambs were weaned at approximately 12 weeks of age and their weight at weaning was recorded.

Diets and feeding

Coarsely milled wheat straw (0.5 to 1 cm) was offered to all ewes at a rate of 780 g dry matter (DM) per day. A concentrate diet was offered at the rate of 400, 150 or 125 g DM per ewe per day for the low, medium and high groups respectively. The concentrate consisted of 42% (kg fresh basis), 300 whole barley, 250 wheat bran, 80 coarsely ground maize, 60 soyabean meal, 14 dibasic calcium phosphate, 5 NaCl and 1 minerals and vitamins mixture. The chemical composition of the straw and concentrate is given in Table 1. Metabolizable energy (ME) contents of the concentrate and the straw were estimated using conventional digestion experiments. Gross energy (GE) content of the two foods and feeds were measured by bomb calorimeter (Farr Instrument Co., Illinois, USA). Metabolizable energy intake (MEI) was calculated as 0.84 digestible energy intake (DEI) intake (Ministry of Agriculture, Fisheries and Food (MAFF), 1987) and DEI was estimated as the difference between GE intake and output in faeces. The creep diet for lambs was formulated to provide a high level of fermentable carbohydrates and protein. It consisted of 92% (kg fresh basis), 450 coarsely ground maize, 130 wheat bran, 100 coarsely ground maize, 300 soyabean meal (LS origin, 480 g crude protein per kg), 13 dibasic calcium phosphate, 5 NaCl and 2 of the same minerals and vitamins mixture as in the concentrate mixture offered to ewes. The grains were hammer milled to pass a 0.57 mm screen. The fixed amount of diet was divided equally into two portions given at 9:00 h and 16:00 h every day. Fresh water and mineral blocks were continuously available.

Measurement of milk yield

Milk yield was estimated using the method of Poort (1982) which involved weighing the lambs before and after sucking and removal of residual milk by hand. The measurement was made over a total of 24 h and repeated weekly over the first 9 weeks of lactation. On the day of measurement, lambs were removed at 20:00 h, and weighed (M1) at 7:00 h next morning before being returned to join their mothers. They were allowed 85 min to obtain milk, weighed again (M2) and the difference (M1 - M2) was assumed to be the amount of milk consumed (suckling yield). Milk remaining in theudder was removed by hand by three well trained shepherds and weighed to the nearest g. Lambs were again removed from their dams after the morning milk yield measurement and the procedure repeated on the same day at 20:00 h to measure milk yield for the other half of the day. The sum of suckling yield and hand milked yield from the two measurements was assumed to be milk yield over the 24-h period. The single weekly estimate of milk yield was assumed to represent the average daily milk yield for the week in which it was measured. Total milk yield for the first 9 weeks of lactation was calculated using the single weekly estimates.

Weighing and health observation

Ewes and lambs were weighed to the nearest 0.25 kg and 0.1 kg respectively, each week at the same time of day before feeding. The health status of ewes and lambs was checked routinely for the incidence of mastitis and scouring. A standard diagnostic procedure (International Dairy Federation, 1981) was used for mastitis and for enteritis.

For most groups, at 2 weeks a later.

Results

Milk yield

Milk yield was significantly higher (P < 0.05) at the rate of 400 g DM per ewe per day but was comparable with the medium and low rates of 150 and 125 g DM per ewe per day. Ewes receiving the medium rate of 150 g DM per ewe per day were significantly (P < 0.05) heavier at weaning than ewes receiving the low rate of 125 g DM per ewe per day. Lambs reared by ewes on the medium rate of 150 g DM per ewe per day were significantly (P < 0.05) heavier at weaning than lambs reared by ewes on the low rate of 125 g DM per ewe per day.
used for the detection of statistical significance while a visual check was practiced to record reading.

For reassessment, the ewes were sampled twice, the first at 2 weeks after lambing and the second 2 to 3 weeks later.

Statistical analysis of data
The following linear model (Peplinski & Ryan, 1984) was used to evaluate the influence of concentrate intake by the ewe and sex of lamb and litter size on changes of ewe body weight, daily milk yield and growth of lambs,

\[ \text{Data} = \mu + N + X + T + e_i, \]

where \( \mu \) is an overall mean associated with each observation, \( N \) is the effect of the sex of lamb, \( T \) is the effect of the sex of the lamb, \( X \) is the effect of the sex of the lamb (single or twins) and \( e_i \) is the residual error assumed to be normally and independently distributed. Reductions in the sums of squares were calculated in order to estimate the effect of given factors adjusted for other factors in the model, then estimable functions were calculated to test the difference among the three levels of feeding, between the two sexes and between singles and twins.

Results
Feed intake
Estimated ME of the concentrate food was 11.21, 13.57 and 15.93 MJ per ewe per day for ewes offered the low, medium and high levels of supplement, respectively. ME intake was the same across treatments (4.45 MJ per ewe per day). Total ME intake from concentrate and straw was estimated to be 16.2, 18.5 and 20.9, respectively, for ewes in the low, medium and high groups, respectively.

Response of ewes and their lambs
Ewes in the high treatment group produced more milk (\( P < 0.05 \)) during the first 9 weeks of lactation than ewes in the low or medium groups. Ewes in the high group returned to immediate post-lambing weight by week 6 whereas ewes of other groups were still below their post-lambing weights at the end of the 12-week suckling period. Total milk yield for the first 9 weeks of lactation was estimated to be 58.54 kg for ewes in the low, medium and high treatments, respectively (Table 2). Milk production peaked 2 weeks after lambing for the medium and high groups and 3 weeks after lambing for the low group. The rate of decline in milk yield was lower in the high treatment than in the other two treatments. Sex of lamb had no influence (\( P > 0.05 \)) on milk yield (Table 3) but there was a trend towards higher milk yield for ewes stockling male lambs. Ewes with two lambs produced more milk (\( P < 0.05 \)) than those with one and maintained a higher level of milk yield throughout the 9 weeks of lactation (Table 3).

Ewes with two lambs tended to lose more weight during weeks 8 to 12 of lactation (Table 4) than those with one lamb. Body-weight change was small for ewes in the high group, which lost significantly less weight (\( P < 0.05 \)) than those in the other two groups (Table 4). No differences were observed in body-weight change between ewes stockling either male or female lambs (Table 5).

Meaning weight and liveweight gain (Table 4) were slightly higher in the high treatment, but differences

Also independent of the concentrate feeding level with similar numbers of lambs across treatments (four, five and five for the low, medium and high treatments, respectively) being recorded during the first 4 weeks of life.

No treatment was given and lambs were allowed to recover naturally.

Discussion

Traditionally, in the Middle East, lactating Awassi ewes are given about 956 g/day of a mixture of barley grain and wheat bran. The lambs remains with the ewe until 10 to 12 weeks of age but some milk is also taken for human consumption. After weaning, the ewes are often milked for a further 60 to 100 days. Milk yield of Awassi sheep under continuous suckling regime in Iraq has been reported by Guirgis et al. (1980) to be 105.4 kg during the first 3 months of lactation and 155.7 kg over 167 days of lactation. Similarly, herbs and Awassi (1990) reported a milk yield of 141.3 kg during 12 weeks lactation. These results suggest that, under traditional feeding systems, Awassi ewes produce a little over 1 kg milk per day. The amount of supplement traditionally provided to lactating Awassi ewes is well below the amounts of 201 and 22.6 MJ ME per day recommended for lactating ewes by MAFF (1987) and National Research Council (NRC, 1985).

Results from the experiment described indicate that the traditional supplement of only 956 g/day severely limits milk production. Mean milk yield over 9 weeks of lactation for the ewes given 956 g/day supplement was recorded at 0.93 kg/day compared with 1.12 and 1.48 kg/day for ewes given 1150 and 1390 g supplement daily. Ewes fed under the traditional system utilize a significant amount of body reserves during lactation and, unless such losses are regained before the next production cycle, subsequent fertility and milk yield will be severely reduced (Peat, 1982). Low feed intakes appear to be the major reason for low milk yield and low fertility and twinning rate reported for Awassi sheep in Arab countries (Galal et al., 1989; Haxby, 1994). Marvagiri et al. (1980) studied the effect of body-weight changes before and after lambing on the performance of Cyprus-fattled Chios and Awassi sheep in Cyprus and found that milk production was highest for ewes on the high level of feeding and Awassi ewes produced more milk than the other two breeds. Awassi sheep in Cyprus produced more milk during the first 90 days of lactation than the local Chios sheep (114.3 v. 105.4 kg) and milked for a longer period (Marvagiri et al., 1980). However in Israel, genetically improved Awassi ewes under good management produced 506 l milk per lactation period of 368 days or 2031 in 96 days (Gootwine et al., 1999). ME from straw and concentrate in the experiment described in this paper were estimated to be 16.2, 18.5 and 20.9 MJ per ewe per day, while recommended allowances for ewes sucking singles and twins are 23.4 and 26.5 respectively (NRC, 1985), during the first 9 weeks of lactation. Requirements for ME for maintenance and production of Awassi sheep can be calculated using data on intakes, milk yield and body-weight change. Energy values of 4.6 MJ/kg for milk and 20 MJ/kg for mobilized body tissue were used (MAFF, 1987). Constant efficiencies of 0.62 for dietary ME and 0.80 for body reserve were also used in the calculation. Estimated ME requirements for a 60 kg ewe sucking a single lamb and losing 58 g body weight per day was 20.4 MJ for the first 8 weeks of lactation. These values are in close agreement with those reported by NRC (1985), after adjusting for body weight changes. In comparison with MAFF (1987), our estimates ill
between their estimates for lactating lowland ewes suckling twins and those suckling singles during the first 6 weeks of lactation. The results presented in this paper show that feeding lactating Awassi ewes an extra 400 g of supplement daily for the first 9 weeks of lactation, or a total of 25 kg food, would increase milk yield over the period by 35 kg. The increased amount of supplement given daily also increased ewe body weight 10 weeks after lambing by 6 kg compared with the traditional feeding regime.

This reduced decrease in body weight during lactation would be expected to improve subsequent reproductive performance in ewes (Parry, 1982). Because the value of 1 kg of milk is about five times the cost of 1 kg supplemental food in Middle eastern countries, the results reported indicate that increasing the amount of supplement given to lactating Awassi ewes by 400 g/day would improve both the economic and biological efficiency of the production system.
