Evidence-based asthma management in children — what’s new?

Peter P Van Asperen, Craig M Mellis, Peter D Sly and Colin F Robertson

The Thoracic Society of Australia and New Zealand has updated its guidelines on corticosteroid use in childhood asthma.

The understanding of childhood asthma has increased substantially since the publication of the Thoracic Society of Australia and New Zealand (TSANZ) position statement The role of corticosteroids in the management of childhood asthma in 2002.1 In particular, recognition of the need for separate asthma management guidelines for children aged 5 years or younger has increased,2 and considerably more clinical research evidence on the role of asthma medications in children has become available. The 2010 revision of the TSANZ position statement provides updated recommendations on the roles of inhaled corticosteroids, oral corticosteroids, leukotriene receptor antagonists and combination medications (inhaled corticosteroids plus long-acting β-agonists) in childhood asthma management based on recently published evidence.3 The role of leukotriene receptor antagonists in the management of childhood asthma has also been addressed in detail in a recent National Asthma Council Australia information paper.4

The National Asthma Council Australia provides a comprehensive overview of the role of preventive treatment in childhood asthma in its Asthma management handbook 2006.5 It advocates a stepwise approach to drug therapy that is based on asthma severity. If control is not achieved using initial preventer therapy, it is important to review the diagnosis of asthma — particularly in children aged 5 years or younger — as many children with recurrent cough are mislabelled as having asthma6 and different wheezing phenotypes require different treatment approaches.2 Before escalating the level of preventer therapy, it is also essential to check the child’s inhaler technique and adherence to treatment. Step-down treatment (“back titration”) is advocated once control has been achieved and sustained for at least 3 months.

Two placebo-controlled studies of montelukast have established the efficacy and safety of this medication and form the basis of its current Pharmaceutical Benefits Scheme listing for children with frequent intermittent or mild persistent asthma.3,4 Compared with placebo, regular montelukast therapy produces a modest reduction in exacerbation risk in children with viral-induced wheezing.3,4 An additional benefit of montelukast therapy is its proven efficacy for protecting against exercise-induced bronchoconstriction,3,4 being more effective than long-acting β-agonists without development of the tolerance seen with long-acting β-agonists.3

Preventer therapy for children who have frequent intermittent or persistent asthma symptoms*

FP = fluticasone propionate. BDP–HFA = beclomethasone dipropionate–hydrofluoroalkane. BUD = budesonide. CIC = ciclesonide. *Modified from the Asthma management handbook 2006 with permission from the National Asthma Council Australia.5 † Long-acting β-agonists not recommended for children aged 5 years or younger.
This information led to the current Pharmaceutical Benefits Scheme listing of montelukast for children aged 6–14 years who have ongoing activity-related asthma despite inhaled corticosteroid treatment. The effectiveness of prophylactic inhaled corticosteroids in persistent childhood asthma is well established. In contrast, regular inhaled corticosteroid treatment for intermittent, viral-induced wheezing does not reduce rates of hospitalisation, use of oral corticosteroids, or frequency and duration of acute episodes. Systemic effects of inhaled corticosteroids in children are well documented; they include impaired linear growth, adrenal suppression, and effects on bone mineralisation. Although the clinical significance of these adverse effects is uncertain, factors such as individual susceptibility, severity of asthma, age, pubertal status, total dose, and dose delivery may affect risk of systemic toxicity.

Although it is common to add a long-acting β-agonist to inhaled corticosteroids (as a single combination inhaler) there are few paediatric studies examining this practice, and these suggest that, while the combination improves lung function, it does not reduce exacerbation risk — in fact, it may increase it. These recent studies support the current National Asthma Council recommendations of reserving the addition of long-acting β-agonists for children with asthma that is not adequately controlled by 200–250 μg/day fluticasone propionate or equivalent doses of other inhaled corticosteroids, and highlight the potential role of montelukast as an alternative add-on therapy. The use of long-acting β-agonists is not, however, recommended for children aged 5 years or younger.

Our recommendations for preventive treatment in childhood asthma are summarised in the Box. Children with infrequent intermittent asthma require no preventive therapy. Current evidence suggests that non-steroidal preventers should be trialled first in children with frequent intermittent or mild persistent asthma, while inhaled corticosteroids are indicated as first-line preventive treatment in children with moderate–severe persistent asthma. Long-acting β-agonists or montelukast are add-on options in children with persistent symptoms despite adequate inhaled corticosteroid treatment.

In terms of acute asthma management, oral corticosteroids improve outcomes in children presenting to hospital with acute asthma, but the efficacy of oral corticosteroids for children aged 5 years or younger with acute, mild–moderate, viral-induced wheezing has been questioned. Based on current evidence, we recommend oral corticosteroids be reserved for children with moderate–severe acute asthma exacerbation and children with an incomplete response to β-agonists. However, in children aged 5 years or younger (particularly those with intermittent, viral-induced wheezing) the use of oral corticosteroids should be limited to those with severe wheeze who require hospital admission; an initial dose of 2 mg/kg prednisolone (maximum 60 mg) is recommended, followed by daily doses of 1 mg/kg if required. Although a 3-day course is generally sufficient, a more prolonged course may be indicated in severe cases. There is some evidence for the benefit of intermittent inhaled corticosteroids and leukotriene receptor antagonists in acute asthma, but oral corticosteroids remain the treatment of choice — particularly for more severe episodes, because of ease of administration, low cost and greater proven efficacy in severe acute asthma. The need for recurrent systemic corticosteroid therapy requires reassessment of the child’s interval therapy, particularly in cases of persistent asthma, and specialist referral.
